Non-steroidal anti-inflammatory drugs: What is the actual risk of liver damage?

Fernando Bessone

Abstract

Non-steroidal anti-inflammatory drugs (NSAIDs) constitute a family of drugs, which taken as a group, represent one of the most frequently prescribed around the world. Thus, not surprisingly NSAIDs, along with antiinfectious agents, list on the top for causes of Drug-Induced Liver Injury (DILI). The incidence of liver disease induced by NSAIDs reported in clinical studies is fairly uniform ranging from 0.29/100 000 [95% confidence interval (CI): 0.17-051] to 9/100 000 (95% CI: 6-15). However, compared with these results, a higher risk of liver-related hospitalizations was reported (3-23 per 100000 patients). NSAIDs exhibit a broad spectrum of liver damage ranging from asymptomatic, transient, hyper-transaminasemia to fulminant hepatic failure. However, under-reporting of asymptomatic, mild cases, as well as those with transient liver-tests alteration, in conjunction with reports non-compliant with pharmacovigilance criteria to ascertain DILI and flawed epidemiological studies, jeopardize the chance to ascertain the actual risk of NSAIDs hepatotoxicity. Several NSAIDs, namely bromfenac, ibufenac and benoxaprofen, have been withdrawn from the market due to hepatotoxicity; others like nimesulide were never marketed in some countries and withdrawn in others. Indeed, the controversy concerning the actual risk of severe liver disease persists within NSAIDs research. The present work intends (1) to provide a critical analysis of the dissimilar results currently available in the literature concerning the epidemiology of NSAIDS hepatotoxicity; and (2) to review the risk of hepatotoxicity for each one of the most commonly employed compounds of the NSAIDs family, based on past and recently published data.
setting evidence indicates that naproxen is associated with a lower thrombotic risk than coxibs, and that ibuprofen has a good thrombolytic safety profile for daily doses of up to 1200 mg. Noticeably, 6% of the US population consumes at least one of these products in a month. Information regarding ibuprofen indicates that 24% is sold as over the counter medication.

The paradox is that even when it has been known historically and widely accepted that the use of these NSAIDs is associated with a low rate of hepatic adverse events, it is severe liver damage that is the main adverse event through which these drugs are eventually withdrawn from the market. On the other hand, 50% of fulminant hepatic failure (FHF) in the USA is due to hepatotoxicity. Antimicrobial drugs are the most often involved.

Hepatotoxicity is more frequently encountered in post-marketing studies or even after, once the drug has already been launched due to the fact that premarketing recruits a relatively low number of patients, frequently insufficient to fully judge the true incidence of hepatotoxicity. One of the most representative examples of this situation is that of bromfenac-related severe liver damage. Bromfenac was withdrawn from the market in 1998 as a result of multiple reports of FHF within the year of its approval (1 case for every 10 000 exposed individuals). Frequent severe liver damage associated with nimesulide had also been reported. Although nimesulide is currently approved in 50 countries worldwide, national health authorities of several countries have withdrawn nimesulide from the market and others have never approved it. EMEA (European Medicines Evaluation Agency) currently recommends a restricted length of treatment (15 d) and a maximal drug dosage (100 mg/d) for nimesulide therapy, which in addition should be avoided in children.

Interestingly, NSAIDs-induced hepatotoxicity may be associated with liver injury six to nine times more frequently in patients who are taking other potentially hepatotoxic medications concomitantly. (i.e. amoxicillin-clavulanic acid, proton pump inhibitor, phenobarbitol, isoniazid). According to a recent study, hepatic steatosis and metabolic syndrome might predispose to an NSAIDs-induced liver toxicity, a similar situation to that already proven for methotrexate and halothane.

Finally, chronic alcohol abuse during treatment with paracetamol was associated with an increase in liver injury induced by acetaminophen including those patients who were taking doses not higher than 4 g daily.

Our attempt in the present work is two-fold (1) to analyze the clinical impact regarding severity of NSAIDs hepatotoxicity based on a critical analysis of the conflicting epidemiological approaches currently available in the literature; and (2) to review the individual expected risk of hepatotoxicity for NSAIDs most commonly employed in clinical practice based on past and recently published data.

**EPIDEMIOLOGY**

Epidemiological studies evaluating severe NSAID liver toxicity take into consideration hospitalization and death of the exposed population. One important pitfall to demonstrate the risk of liver damage induced by NSAIDs resides in the epidemiological study design.

Generally speaking, the strengths of randomized control trials (RCT) are the close patient follow up, the comparison with a control group and an accepted design in order to prove specific therapeutic actions. However, RCT frequently represent just a sample of the general population seldom truly representative, particularly as evidence of the incidence of hepatotoxicity. In addition, trials frequently fail to be informative concerning populations under 18 years of age because this group of individuals is usually underrepresented when not openly excluded. On the other hand, data regarding incidence of liver toxicity from cohort, case-control studies and trials are not free from bias. Environmental factors, alcohol abuse, viral infections and metabolic factors coexist with DILI constituting confounding factors. Likewise, retrospective studies have important drawbacks such as researcher unawareness of concurrent drug intake other than the study drug. Other important limiting factors affect both pre- and post-marketing hepatotoxicity studies. Among these is the fact that mild and reversible cases are underreported. The other frequent source of error is the lack of a reliable “denominator” (defined as the number of patients potentially exposed) for calculations. We may also consider an additional source of underestimation of hepatotoxicity which is the report lag - the delay between the occurrence of adverse events and case communication. The latter should be taken into account when the alert is associated with severe liver damage. The incidence of liver disease induced by NSAIDs reported in most studies is fairly uniform ranging from 1 to 9 cases per 100 000 persons exposed. In spite of these results, epidemiologists analyzing the real risk of liver disease induced by different NSAIDs usually face difficulties, such as different study designs, different populations (ethnic groups, age and sex) and adjustment variable control methods that add complexity to the data analysis.

Traversa and co-workers analyzed a retrospective study from 1997 through 2001 in a region of Italy (850 000 inhabitants). About 2 million prescriptions corresponding to NSAIDs-treated patients through a 5-year period follow-up were analyzed.

One of the main conclusions drawn from this study is that the risk of NSAIDs induced hepatotoxicity is very small (if the number of prescriptions is taken as the denominator, the incidence of liver injury was 1.7 per 100 000 exposed individuals). In contrast, a higher rate of hepatotoxicity was observed among people older than 75 years old (5.7-fold increase of risk of liver disease when compared with people under 45 years). Interestingly, it was observed that nimesulide showed both a slightly higher incidence of liver damage and a higher hospitalization rate than that observed with the other NSAIDs (33 per 100 000 patient-years vs 22 per 100 000 patient-years respectively). The authors were unable to find severe liver damage and deaths related to NSAIDs. While the positive features of this study were the high number of patients

---

**References**

enrolled and the extended follow-up, the major limitations were that the database monitoring system neither included the reason for prescription nor NSAIDs doses.

In contrast, a case-control study that included prescriptions of all market-approved NSAIDs highlighted diclofenac as the only drug associated with an increased risk of liver damage (95% confidence interval: 1.9-8.8)\[^{28}\]. Laine and co-workers recently reported the largest prospective, randomized double-blind study comprising four times more patients than the largest previous trials. They evaluated the incidence of diclofenac-induced hepatotoxicity in 17,289 patients, showing that patients who suffered diclofenac-associated adverse drugs reactions seldom required hospital admission (23/100,000 patients). They also observed that symptoms of diclofenac-related liver disease developed either early or late after starting drug therapy\[^{29}\]. The conclusions were: a low rate of occurrence of diclofenac-related admissions, and a very low rate of diclofenac-associated FHF. Indeed, only one patient required liver hospitalization for every 132 patients with aminotransferase > 3 × upper limit of normal (ULN).

Rostom and co-workers investigated bibliographic databases MEDLINE and EMBASE and public FDA archives in order to identify randomized controlled trials of diclofenac, naproxen, ibuprofen, celecoxib, rofecoxib, valdecoxib, or meloxicam in adults with osteoarthritis or rheumatoid arthritis. The authors analyzed aminotransferase elevations > 3 ULN, liver-related drug discontinuation, serious hepatic adverse events, liver-related hospitalizations, and liver-related deaths\[^{21}\]. After analyzing 65 database articles and 67 FDA submitted studies, they concluded that diclofenac and rofecoxib had a higher level of transaminases both compared with placebo and with the other studied NSAIDs. Interestingly, none of these studies had a high rate of serious hepatic adverse events, hospitalizations or death.

The authors found only 1 hospital admission (naproxen) observed among 37,671 patients included in studies reporting hospitalization. This very low hospitalization rate represents 3 per 100,000 patients (0.5-15 per 100,000 patients). One patient died due to naproxen liver toxicity among 51,942 patients consuming NSAIDs, which in turn also represents a low death rate: 2 per 100,000 patients (0.3-11 per 100,000 patients).

These results are in concordance with those reported by Rubenstein and Laine who also analyzed several epide-

### CHARACTERISTICS OF NSAIDS INDUCED LIVER TOXICITY

The discovery of aspirin in 1946 followed by that of phenylbutazone was the beginning of the NSAIDs era. However, not until 1960 was indomethacin marketed. On the other hand, during the 1950s, ibuprofen was the second drug (along with aspirin) approved to be sold as over the counter medication. Interestingly, most of these substances were employed during the 60s, before the prostaglandin era.

The NSAIDs chemical classification recognizes four major groups of molecules: (1) carboxylic acids; (2) oxycams carboxamides; (3) sulphonanilides diaryl-substituted; and (4) pyrazole/furanones\[^{29}\]. From the clinical stand point NSAIDs induced hepatotoxicity is associated with

different patterns of clinical presentation, several mechanisms of liver damage and various pathological patterns.

We will only describe below the clinical characteristics of several NSAIDs that may be associated with a potential liver injury (Table 2).

Acetaminophen was not taken into account because most cases of liver damage are due to suicide attempts but a minority of cases are accidental and related to use of paracetamol as a therapeutic prescription. Acetaminophen-induced hepatotoxicity should be described separately and not within this topic.

**ASPIRIN**

Although liver toxicity induced by aspirin is considered to be dose-dependent, there is evidence that rheumatic patients may have predisposing conditions that may increase individual risk of liver damage. Hypoalbuminemia in patients with systemic lupus erythematosus and juvenile rheumatoid arthritis are two well documented risk factors for increased susceptibility to liver injury[30,31]. In addition, studies in rats have shown that aspirin hepatotoxicity is more common in animals with experimentally-induced rheumatoid arthritis compared to that observed in those without arthritis[32]. The clinical presentation of liver toxicity is often anicteric (jaundice at less than 5%) and transaminase levels correlate with serum salicylate levels (> 25 mg/100 mL)[33]. Focal nonspecific necrosis, hepatocellular degeneration and hydropic changes are commonly seen in liver histology[34]. Aspirin can also produce a mitochondrial dysfunction pattern that may lead to a liver free fatty acid accumulation and subsequently develop into a severe metabolic disorder associated with hepatic massive microsteatosis. This syndrome, known as Reye’s Syndrome, is characterized by metabolic acidosis, hepatic encephalopathy, hypoglycemia, coagulopathy and azotemia. Reye’s disease induced by aspirin is a rarity since aspirin is currently avoided in pediatric patients and replaced by ibuprofen and paracetamol.

A recent experimental study in rats suggests that salicylic acid could trigger mitochondrial dysfunction causing a marked fall in intracellular ATP which in turn leads to a lethal hepatocellular injury mediated by a lipid peroxidation mechanism[35].

**DICLOFENAC**

Diclofenac is the most widely used NSAID in the world[36,37]. The vast majority of data related to hepatic reactions comes from retrospective studies. There were no more than 60 cases of diclofenac hepatotoxicity reported in the literature until Banks and co-workers in 1995 reported their analysis of 180 cases referred to FDA from 1988 through 1991. The authors observed evidence of liver disease in 85% of the patients within the first 6 mo after drug intake. Interestingly, a higher latency (after 6 mo) was observed in 12% of cases[38]. The long latency period observed in a large number of cases in addition to the absence of hypersensibility support a metabolic mechanism of hepatotoxicity. Jaundice was a very common sign present in 90 out of 120 patients. A total of 7 jaundiced patients died as a result of liver disease. In this analysis liver function tests (LFTs) showed a mixed (hepatocellular and cholestatic) pattern in 66% of cases, cholestatic in 8% and indeterminate in the remainder of the group. In contrast to Jick’s point of view which suggests that hepatotoxicity induced by diclofenac is an uncommon event[39], the study by Banks proposed for the first time that diclofenac is a much more common cause of liver damage than so far suspected[40]. This concept was reinforced in a recent report from Laine who conducted the longest and largest liver-related diclofenac study so far ever reported [Multinational Etoricoxib and Diclofenac Arthritis Long-Term (MEDAL) program][41]. They conducted a prospective, randomized and double-blind study analyzing the frequency of diclofenac induced liver reactions in 17 289 patients. The authors randomized only those osteoarthritis or rheumatoid arthritis patients over 50 years of age who were going to receive diclofenac therapy (150 mg daily) or etoricoxib (60 or 90 mg daily). They also excluded cases with previous liver disease or more than 14 weekly alcohol drinks. Hypertransaminasemia (ALT values higher than 10 × ULN) was observed in over 3% of arthritic patients with a regular intake of diclofenac. It is interesting to point out that alanine transaminase (ALT) values higher than 10 × ULN were only identified in 0.5% of cases[42]. The incidence of diclofenac liver-related hospitalizations in this study was 16 per 100 000 patient-years. Through these results, the authors provide evidence that diclofenac is a very safe drug. The

small number of related hospitalizations (0.023%), and 
Hy's cases (transaminases > 3 ULN and bilirubin > 2 
ULN or a fatal outcome or liver transplantation) (0.012%) 
are the strongest evidence showing that diclofenac bears a 
low liver toxicity rate.

These data are in concordance with those observed by 
Traversa and co-workers showing ibuprofen and naproxen 
also displayed a low hepatotoxicity rate. However, in 
this latter study nimesulide had a higher hospitalization 
rate when compared with a past control cohort (33 per 
100 000 patient-years)\(^\text{[28]}\). In a systematic analysis of 
several randomized studies, Rostom and co-workers also 
found a very low frequency of hospital admissions due 
to NSAIDs related-liver disease in 4261 patients (3 per 
100 000 patient) and 0% when diclofenac was evaluated separately\(^\text{[20]}\).

Diclofenac is a typical example of the combination 
of factors resulting in hepatotoxicity (e.g. drug metabo-
limism, reactive metabolite formation and clearance) deter-
mining the actual development and the severity of 
liver damage. Moreover, diclofenac might produce liver injury 
through either metabolic idiosyncrasy or an immunologi-
cal mechanism generated by drug adduct formation\(^\text{[8]}\).

**SULINDAC**

Sulindac (SLD) is associated with an increased incidence 
of liver toxicity and serious hepatic reactions (5-10 times) 
when compared with other NSAIDs. Besides its recog-
nized anti-inflammatory mechanism through the inhibit-
on of cyclooxygenase (COX 1 and 2), SLD became very 
popular due to its antiapoptotic effect in colonic polyposis 
treatment\(^\text{[40]}\). SLD induced hepatotoxicity was more fre-
quently encountered among people over 50 years old.

Regarding the mechanism of hepatotoxicity, SLD associated 
DILI is one other example of a combination of factors as 
judged by the conflicting results present in the literature. 
Indeed, in a series of 91 documented cases reported to 
FDA a predominantly cholestatic pattern was present in 
43% while hepatocellular-related changes were found in 
25% of patients\(^\text{[40]}\). Moreover, a hypersensitivity mechanism 
of liver injury was present in 60% of cases. Zou et al\(^\text{[43]}\) re-
cently reported an interesting pilot study showing that 
treatment of SLD and lipopolysaccharide (LPS) caused 
liver injury in rats. In this context they also found a selec-
tively clotting system activation and fibrinolytic system 
inhibition in rats treated with SLD/LPS. These changes 
were also associated with tisular hypoxia and fibrin clot 
deposit in the hepatic sinusoids\(^\text{[40]}\). Researchers suggest 
that these results may be extrapolated to humans with the 
disease. Furthermore, they hypothesize that hypoxia in 
the frame of the SLD/LPS association may underlie the 
idiosyncratic model where the sulfide metabolite probably 
plays a central role.

Another experimental study carried out by the same 
authors shows that tumor necrosis factor (TNF-\(\alpha\)) aug-
mented the cytotoxicity of SLD sulfide in primary hepatopa-
cyes and HepG2 cells. These results suggest that TNF-\(\alpha\) 
can enhance SLD sulfide-induced hepatotoxicity, thereby 
contributing to liver injury in SLD/LPS-cotreated rats\(^\text{[48]}\).

Regrettably the current coexistence of conflicting 
and heterogeneous results precludes us from reaching 
valid conclusions regarding SLD DILI.

**IBUPROFEN**

Ibuprofen has a recognized anti-inflammatory, analgesic 
and antipyretic property and is one of the most com-
monly NSAIDs used worldwide. It is characterized by a 
high safety profile and very low liver toxicity incidence. 
Along with paracetamol and aspirin, ibuprofen has be-
come one of the largest ever selling over the counter 
drugs. It was first introduced to the UK market in 1969 
and due to the low rate of gastrointestinal adverse events, 
it has ever since almost replaced aspirin, indometacsin 
and phenylbutazone in arthritic patients\(^\text{[49]}\). A scarce number 
of hepatotoxicity reports involving ibuprofen were pub-
lished, associated to both hepatocellular and cholestatic 
liver damage. Indeed, one of the latter cases was linked 
to vanishing bile duct syndrome\(^\text{[49,46]}\). It has also been sug-
ggested that ibuprofen may increase the risk of liver injury 
when administered to patients with chronic hepatitis C. 
An ibuprofen associated increase of transaminases > 5 × 
UNL was recently reported in three patients with chronic 
hepatitis C, eventually confirmed by re-challenge\(^\text{[47]}\).

Traversa et al\(^\text{[23]}\) in their cohort study that recruited 
thousands of patients receiving various NSAIDs con-
firmed that ibuprofen has a very low liver toxicity rate: 
Only two patients showed ibuprofen-associated liver injury 
(out of 126 cases that had NSAIDs). Despite the massive 
use of this drug worldwide, a low rate of ibuprofen liver 
toxicity along with a low incidence of gastrointestinal, 
renal and cardiovascular serious events charactersizes the 
safety profile. This is probably based on the fact ibuprofen 
has a short plasma half life and does not form pathologi-
cal metabolites. The absence of reports including ibupro-
fen induced liver injury in several studies and meta-
analyses, strongly suggests that ibuprofen is an unlikely cause of 
liver disease\(^\text{[48,50]}\).

**COXIBS**

Coxibs are NSAIDs designed to selectively inhibit 
COX-2. Lately, this group of drugs has been gaining 
worldwide popularity due to a much better gastrointes-
tinal safety profile when compared with nonselective 
NSAIDs\(^\text{[25]}\). However, NSAIDs-induced cardiovascular 
adverse events have generated significant controversy\(^\text{[47,52]}\). 
Due to increased risk of myocardial infarction and arterial 
hypertension, rofecoxib was removed from the market 
by Merck in 2004\(^\text{[33]}\). Valdecoxib was also voluntarily dis-
continued by manufacturer Bextra, Pfizer Canada Inc and 
by FDA in 2005 because of severe allergic skin lesions 
including cases of Stevens-Johnson syndrome and also 
because of an increased risk of heart and stroke attack\(^\text{[50]}\). 
On the other hand, celecoxib continues to be marketed in 
many countries. Laine and coworkers recently published 
a comprehensive evaluation of the literature up to 2007
analyzing controlled trials, meta-analyses and reviews related to the safety profile of selective inhibitors of COX-2 in patients with osteoarthritis (OA) [56]. Their results are truly encouraging and show that coxibs have a therapeutic efficacy comparable to other NSAIDs and higher than that of acetaminophen. This was observed when patients with OA were treated for moderate to severe degree of pain. Through meta-analysis the authors documented that coxibs have a 74% lower risk of gastro-duodenal ulcer complications. In contrast, they found a double risk of myocardial infarction vs placebo and naproxen treated patients. There were no significant differences in cardiovascular risk between coxibs compared with non-naproxen NSAIDs. Despite these encouraging results, FDA reported an alert related to the increase of cardiovascular risk induced by coxibs.

Coxib-induced liver injury is an uncommon event and the annual reported incidence of hepatotoxicity is 1 in 100000 exposed persons [56]. A long term study evaluating the safety profile of celecoxib in arthritis patients (Celecoxib Long-term Arthritis Safety Study-CLASS) found increased transaminase level in 0.6 % patients [57].

A rise of transaminase level was also reported and associated with rofecoxib (2%) and with higher doses of lumiracoxib (3%). In this study, a higher frequency of clinical hepatitis was found in patients receiving 400 mg of lumiracoxib when compared with ibuprofen and naproxen treated patients [58]. In another survey, lumiracoxib was linked to severe hepatocellular necrosis [59]. Health authorities from United Kingdom subsequently removed it from the market. Scottish authorities reported 20 cases of severe liver disease probably associated with lumiracoxib. FHF was documented in 14 out of 20 patients (two patients died and three patients needed liver transplantation). In addition, recent postmarketing reports from Australia of severe hepatic reactions with lumiracoxib at doses of at least 200 mg (two patients died and 2 underwent liver transplantation) led also to its withdrawal from the market in that country [60].

On the other hand, rofecoxib was associated with a low rate of hepatic reactions and an increase of ALT ≥ 3 × UNL was documented in 1.8/100000 exposed persons [58], but despite this excellent safety profile, Yan and colleagues reported two well-documented cases of cholestatic hepatitis induced by rofecoxib [61]. The first patient showed a high level of alkaline phosphatase (APH) associated with hepatocellular injury in zone 1 whereas in the other case a significant increase in ALT associated with a minimum increase of APH was documented. In this latter patient mild liver damage in both acinar zones 1 and 3 was described. In contrast, four other published cases of rofecoxib induced liver toxicity were characterized by predominant cholestatic presentation [59,60].

To our knowledge no case of etoricoxib severe hepatotoxicity has ever been published. However, transaminase elevation (3 × ULN) has been reported in 1% of patients treated with etoricoxib for up to one year [21,64]. The mechanism of liver damage induced by coxibs has not yet been completely elucidated. Kung and co-workers recently suggested that the bioactivation of lumiracoxib and its metabolite [4'-hydroxylumiracoxib (M5)] may produce GSH depletion, covalent binding to proteins and oxidative stress, that in turn may lead to liver injury [65].

Nevertheless, hepatotoxicity caused by non-selective NSAIDs has been more extensively studied. Furthermore, mitochondrial injury, cholestasis and oxidative stress induced by a reactive metabolite formation constitute the most conspicuous molecular reported disorders. An attractive hypothesis suggests that NSAIDs inhibition of COX-2, might cause liver damage through a prostaglandin (PGs) pathway. Regarding this concept the authors proposed that the inhibition of PGE2 could down regulate the antiapoptotic mitochondrial protein Bel-2, which protects against bile acid induced apoptosis [66].

OXICAMS

Oxicams induced hepatotoxicity is an uncommon clinical situation. Piroxicam induced severe hepatocellular necrosis was the most frequent reported clinical pattern [35,67-69]. Uneventful recovery, death and need of liver transplantation have all been reported [69,70]. On the other hand, a clinical and histological pattern of hepatocellular plus cholestatic (mixed) injury was also associated with piroxicam in one single case. LFTs normalization was observed in this patient within 4 mo after starting the clinical disease [71]. Interestingly, a case of severe intrahepatic cholestasis linked to a long period of piroxicam intake, was originally described 20 years ago [2].

Only two patients with piroxicam-induced liver toxicity were admitted to our liver unit during the last three decades (unpublished data). The first patient was a 44-year-old woman with clinical and histological evidence of submassive necrosis. The patient developed ascites and liver failure after 28 d of drug intake and uneventfully recovered without liver transplantation in 95 d from clinical onset. The other case was a 42-year-old man admitted with clinical and biochemical manifestations of severe cholestasis after piroxicam treatment as the single medication for 58 d. Liver histology showed a typical hepatocanicular cholestasis associated with ductopenia (Figure 1). This latter case progressively evolved to prolonged cholestasis with ascites, anorexia and intolerable itching. He underwent corticosteroids therapy for 30 d. We were able to document a complete biochemical recovery 120 d from the clinical onset.

Other oxicam derivatives were also occasionally implicated in cases of acute cholestatic hepatitis included isoxicam and droxicam [73].

The mechanism of oxicams-induced hepatotoxicity appears to be idiosyncratic and dose independent. Due to the absence of immunological features in most of the reported cases, it is very difficult to support an immune-mediated mechanism of liver injury [74].

NIMESULIDE

Nimesulide has analgesic, anti-inflammatory and anti-
pyretic activity due to potent inhibitory effects on the COX-2 enzymes. Nimesulide bears a good gastro-intestinal tolerance. The mechanism of action has been attributed to a unique chemical structure of the sulphonanilides class of NSAIDs[75].

Our group in Argentina reported the first observation linking nimesulide with liver toxicity in 1997[76]. Since then, a steady flow of reports confirmed severe forms of hepatotoxicity, to the point that national health authorities of several countries withdrew nimesulide from the market[77-88]. Despite this, nimesulide commercialization is still maintained in several European countries, although the EMEA reports recommend a length of therapy restricted to 15 d and maximal dosage of 100 mg/d[13]. Controversy regarding nimesulide persists due to the fact that clinical series reports and epidemiological trials continue to involve nimesulide in severe liver damage[19,89,90]. In agreement with the recent publication by Walker et al[96], this subpopulation was composed predominantly of females older than 50 years. Two patients died before liver transplant due to multiorgan failure, while a 9-year-old girl successfully underwent orthotopic liver transplantation.

Nine patients in our series developed severe liver disease and FHF was observed in 6 cases. In agreement with the recent publication by Walker et al[96], this subpopulation was composed predominantly of females older than 50 years. Two patients died before liver transplant due to multiorgan failure, while a 9-year-old girl successfully underwent orthotopic liver transplantation.

We observed a wide range of variations of ALT/aspartate transaminase level in concordance with Bjarnason who analyzed 33 case reports documenting an elevation of ALT of at least 2-fold in 100%, and a 5-fold elevation in 89% of patients[97].

Nimesulide hepatotoxicity shows a wide spectrum of liver damage including acute hepatitis, cholestasis, mixed forms, massive and submassive hepatic necrosis. We found hepatocellular necrosis (Figure 3) in 64%, cholestatic hepatitis in 27% and pure cholestasis in 9%[94]. The mechanism of nimesulide induced hepatotoxicity remains unknown. It has been suggested that it could be due to the formation of a reactive metabolite. On the other hand, individual genetic variations in drug metabolism have also been proposed.

Acknowledging the true impact of nimesulide on the liver is not an easy task. Despite the proliferation of reports describing nimesulide-induced severe liver injury (mainly Argentina, Ireland and Finland), the epidemiological studies have almost unanimously concluded that severe hepatotoxicity is of low incidence determining a positive risk-benefit ratio. Inquiring about nimesulide intake should be incorporated into standard anamnesis of liver disease, especially when acute liver damage is being investigated.

**Addendum**

Other than the previously analyzed drugs, indomethacin,
naproxen, meloxicam, tenoxicam and etodoloc have also been associated with various hepatic reactions\textsuperscript{10,14}.

**CONCLUSION**

Aspirin was the first discovered NSAID. Dose dependent liver injury is accepted as the prevalent mechanism. Liver toxicity rate is very low currently since aspirin has been replaced by paracetamol and ibuprofen in pediatric patients and in various rheumatic diseases.

Diclofenac is probably the most used NSAID in rheumatology. Severe liver reactions and diclofenac hospitalization rate are uncommon. An increase in ALT levels of 3-10 × ULN is observed in 3% of cases.

Sulindac induced hepatotoxicity was documented more than fifty years ago. Liver damage occurrence was reported to be 5-10 times higher than that of other NSAIDs. A hypersensitivity mechanism of liver injury was the most prevalent liver reaction.

Ibuprofen has the highest liver safety profile among NSAIDs and showed no severe liver injury in larger studies. Along with paracetamol and aspirin, it is considered one of the most common over the counter NSAIDs sold in the world.

Coxibs have currently replaced several NSAIDs due to safer G1 profile. However, the high rate of cardiovascular events associated to rofecoxib is the main drawback related to drug marketing. Despite liver damage being a rare clinical situation, lumiracoxib has been discontinued in several countries due to severe hepatotoxicity.

Oxicams are associated with a well-documented hepatic safety profile. Uncommonly, piroxicam may cause severe hepatocellular damage. The clinical and historical pattern may be mixed or associated to clinical and biochemical prolonged cholestasis with or without ductopenia. Isoxicam and droxicam were only linked to liver toxicity in sporadic reports. The mechanism of liver damage appears to be an idiosyncratic one.

Nimesulide was removed from the market in several countries due to severe liver damage described in clinical series, but various epidemiological surveys do not document these findings. EMEA recommends that nimesulide should only be used for short periods at daily doses not higher than 200 mg/d in adults.

In summary, neither documenting the possibility of the causative role of a drug when confronting liver damage in an individual patient nor determining the true incidence of NSAIDs induced hepatotoxicity in the general population, are easy tasks. Rigorous data collecting, caution and clinical commitment are required when judging potential hepatotoxicity. The clinician always needs to critically evaluate the possibility whether other factors may play a role in the actual findings.

Despite the shortage of well-designed epidemiological studies, there is evidence showing that most of the NSAIDs are safe drugs with low risk of liver injury (mostly ranging from 0.29-3.1/100000 exposed individuals when recent based-population studies were analyzed).

Both sulindac and nimesulide have been linked to a higher frequency of liver damage. NSAIDs induced liver injury which might potentially lead to a fatal outcome or need liver transplantation. As in other forms of DILI, jaundice entails poor prognosis with 25% of jaundiced patients developing severe liver disease. Drugs with an increased risk of liver damage should undergo close LFTs monitoring in order to prompt drug withdrawal to avoid severe hepatotoxicity.

**ACKNOWLEDGMENTS**

I would like to thank Professor Luis Colombato for his support and for reviewing this manuscript and to Professor Miguel Bruguera for his counsel and advice.
